Abstract

We continue the analysis of quantum-like description of markets and economics. The approach has roots in the recently developed quantum game theory and quantum computing. The present paper is devoted to quantum bargaining games which are a special class of quantum market games without institutionalized clearinghouses.

PACS numbers: 02.50.Le, 03.67.-a, 03.65.Bz

1 Quantum bargaining

There have recently been important changes in the paradigms of economics: economists discuss the role of the Heisenberg uncertainty relation [1] or even dare claim that quantum mechanics and mathematical economics are isomorphic [2]. These shocking changes have probably been brought about by the emergence of econophysics. Research on quantum computation and quantum information allows to extend the scope game theory for the quantum world [3, 4]. Among various proposed qualitative scientific methods only quantum

theory does not allow to take no account of the news phenomenon so persistent in social sciences [22]. Therefore the quantum-like description of market phenomena has a remarkable chance of gaining favourable reception from the experts. On the other hand only thorough investigation may reveal if economics already is in or would ever enter the domain of quantum theory. The present authors have given a general description of quantum market games (q-games) in a recent paper, [5]. Among them one may distinguish the class of quantum transactions (q-transactions) that is q-games without institutionalized clearinghouses. This class comprises quantum bargaining (q-bargaining) which are discussed in the present paper and quantum auction (q-auction) to be discussed in a separate paper. The participants of a q-bargaining game will be called Alice (A) and Bob (B). We will suppose that they settle beforehand who is the buyer (Alice) and who is the seller (Bob). A two-way q-bargaining that is a q-bargaining when the last condition is not fulfilled, will be analyzed in a separate paper. Alice enter into negotiations with Bob to settle the price for the transaction. Therefore the proper measuring apparatus consists of the pair of traders in question. In q-auction the measuring apparatus consists of a one side only, the initiator of the auction.

2 The Riemann sphere of polarization states

We will identify the space of Alice polarization states with the one dimensional complex projective space $\mathbb{CP}^1$. Points in $\mathbb{CP}^1$ will be called polarizations (or q-bits [6]). We will use the projective coordinates $\xi = (\xi_0, \xi_1)$. In fact, we will introduce a two dimensional Hilbert space $\mathcal{H}_s$ and choose an orthonormal basis ($|0\rangle, |1\rangle$), $|\xi\rangle = \xi_0|0\rangle + \xi_1|1\rangle \in \mathcal{H}_s$. The scalar product of two vectors $|\xi'\rangle, |\xi''\rangle \in \mathcal{H}_s$ is given by

$$\langle \xi' | \xi'' \rangle = \bar{\xi}'_0 \xi''_0 + \bar{\xi}'_1 \xi''_1 = \bar{\xi}' \cdot \xi'' . \quad (1)$$

where $\bar{\xi}_k$, $k = 0, 1$ denotes the complex conjugate of ξ_k . The proportional vectors $|\xi\rangle$ and $t|\xi\rangle$ ($t \in \mathbb{C} \setminus \{0\}$) will be identified. If we perform the transition from the homogeneous coordinates to the non-homogeneous ones, $\underline{\xi} = (\xi_0, \xi_1) \rightarrow (1, z = \frac{\xi_1}{\xi_0})$, $(0, \xi_1) \rightarrow \infty$, then the projective space $\mathbb{CP}^1$ may be identified with the compactified Gauss plain $\overline{\mathbb{C}}$. A point $z \in \overline{\mathbb{C}}$ may in turn be identified with a point in the two dimensional sphere S^2 . This identification

is given by the bijection $\mathcal{H}_s \rightarrow S^2$

$$S^2 \ni (x_1, x_2, x_3) =: \vec{r}(\xi) = \frac{\langle \xi | \vec{\sigma} | \xi \rangle}{\langle \xi | \xi \rangle}, \quad (2)$$

where $\vec{\sigma} := (\sigma_1, \sigma_2, \sigma_3)$ and σ_1, σ_2 and σ_3 are the Pauli matrices. The mapping (2) is called Cayley-Klein parameterisation. We will use all the three equivalent descriptions $\mathbb{CP}^1 \simeq \overline{\mathbb{C}} \simeq S^2$ of the space of polarization states but one must remember that the superposition (addition) of polarization states may only be performed in the Hilbert space $\mathcal{H}_s$ [6]. The probability of measuring the strategy $|\xi''\rangle$ in the state strategy $|\xi'\rangle$ is given by squared module of the scalar product (1) of the states and may be expressed in terms of the angle α between the corresponding unit vectors $\vec{r}(\xi'), \vec{r}(\xi'') \in \mathbb{R}^3$ (that is in S^2) by the formula

$$\frac{|\langle \xi' | \xi'' \rangle|^2}{\langle \xi' | \xi' \rangle \langle \xi'' | \xi'' \rangle} = \frac{1 + \vec{r}(\xi') \cdot \vec{r}(\xi'')}{2} = \cos^2 \frac{\alpha}{2}.$$

Points in the Riemann sphere, $z \in \overline{\mathbb{C}}$, are in the following 1-1 correspondence with projective operators $P_{\vec{r}}$ acting on the Hilbert space $\mathcal{H}_s$:

$$P_{\vec{r}(\xi)} |\xi'\rangle := \frac{\langle \xi | \xi' \rangle}{\langle \xi | \xi \rangle} |\xi\rangle.$$

They are usually written as $P_{\vec{r}(\xi)} = \frac{|\xi\rangle\langle\xi|}{\langle\xi|\xi\rangle}$. In the orthonormal basis $(|0\rangle, |1\rangle)$ the projectors take the matrix form $P_{\vec{r}}$:

$$P_{\vec{r}} = \frac{I + \vec{r} \cdot \vec{\sigma}}{2}, \quad (3)$$

where I is the unit matrix. This representation is referred to as the Stokes parametrization [7] and is the inverse one to the Cayley-Kleina parametrization (2). We will use the following interpretation of the Alice polarization state $|\xi\rangle_A \in \mathcal{H}_{sA}$ (that is of her strategy). If she formulates the conditions of the transaction we say she has the polarization 1 (and is in the state $|\vec{r}\rangle_A = |1\rangle$). In q-bargaining this means that she put forward the price. In the opposite case, when she decides if the transaction is made or not, we say she has the polarization $|0\rangle$. (She accepts or not the conditions of the proposed transaction.) This is an analogy of the isospin symmetry in nuclear physics which says that nucleon has two polarization states: proton and neutron. The vectors $(|0\rangle, |1\rangle)$ form an orthonormal basis in $\mathcal{H}_s$, the linear hull of possible Alice polarization states. Bob's polarization is defined in an analogous way.

3 Polarizations of q-bargaining

The states representing Alice and Bob strategies are fermions from the physical point of view. This seemingly surprising statement consist in noticing that the transaction in question is made only if the traders have opposite polarizations (and even that is not a guarantee of the accomplishment). Obviously, the states of Alice and Bob became entangled if they enter into q-bargaining. The reduction of the state $|\xi\rangle_A$ (Alice) to $|1\rangle_A$ or $|0\rangle_A$ always results in Bob winding up in in the state $|0\rangle_B$ or $|1\rangle_B$, respectively. Therefore the space of polarizations of q-bargaining is isomorphic to the space of polarizations of a single participant of the bargaining in question ($\mathbb{CP}^1$). The homogeneous coordinates of polarizations of q-bargaining, that is a two dimensional complex Hilbert space $\mathcal{H}_s \subset \mathcal{H}_{sA} \otimes \mathcal{H}_{sB}$, is spanned by two orthonormal vectors $|10\rangle := |1\rangle_A |0\rangle_B$ and $|01\rangle := |0\rangle_A |1\rangle_B$. A market process resulting in q-bargaining is described by a projection $P_{|1\rangle} : \mathcal{H}_{sA} \otimes \mathcal{H}_{sB} \rightarrow \mathcal{H}_s$. The result of the projection depends on the choice of the basis ($|0\rangle, |1\rangle$) (it is sufficient to point out the vector $|0\rangle$). We will suppose that the polarization of q-bargaining is determined by the pair of participants in a unique way.

This polarization space has a fascinating connection to Lorentzian geometry (special relativity). We cannot help noting here that, according to Penrose [20, 21], $\mathbb{CP}^1 \simeq S^2$ may be identified with the heavenly sphere of light rays coming to an observer. The group of conformal transformations of the Riemann sphere $PSL(2, \mathbb{C})$ is isomorphic to the proper Lorentz group $SO_0(3, 1)$ that preserves the Minkowski metric. Penrose have also shown that the points on the heavenly sphere may be obtained from spinors so that any point on the heavenly sphere corresponds to a proposition specifying the state of a spinor (in the space of propositions in the quantum logic associated to the Jordan algebra $h_2(\mathbb{C})$).

The arguments given in the following paragraph show that the state $|01\rangle$ is more profitable for Alice than the state $|10\rangle$. The skill of replication of the vector $|0\rangle$ would allow Alice avoiding winding up in the state $|10\rangle$. But quantum cloning is not possible [8] and this makes the quantum bargaining nontrivial and very interesting. It seems worth to notice that although the polarization state cannot be cloned it may be transferred. We may by using classical and quantum communication channels [9, 10] teleport Alice polarization state to another q-bargaining site. In that way Alice may enter

into negotiation with Bill instead of Bob. Nevertheless, she will not be able to accomplish both transaction simultaneously. This seems to be natural if one recalls the common belief in undividity of attention. Alice however may multiply her profits during a fixed interval by using financial oscillators [11]. To this end she must be able to master validity times of various financial instruments bought or sold in q-bargaining at different times.

We will say that Alice polarization $|\xi\rangle_A$ *dominates* Bob' one $|\xi\rangle_B$ ($|\xi\rangle_A \succ |\xi\rangle_B$) during q-bargaining with the polarization $|o\rangle$ if the probability of being in the state $|o\rangle$ is greater for Alice than for Bob, that is

$$|\xi\rangle_A \succ |\xi\rangle_B \Leftrightarrow \frac{|\langle o|\xi\rangle_A|^2}{A\langle \xi|\xi\rangle_A} > \frac{|\langle o|\xi\rangle_B|^2}{B\langle \xi|\xi\rangle_B} \Leftrightarrow x_{3A} < x_{3B}.$$

This definition is justified by the asymmetry of profits made on a deal by the same party having different polarizations $|o\rangle$ and $|1\rangle$. More detailed analysis of possible profits will be presented in the following paragraph. Of course, if the polarizations are the same then the relation of dominance is transitive. If we consider three parties A , B and C and every pair of them enters into a q-bargaining then we have

$$(|\xi\rangle_A \succ |\xi\rangle_B \text{ and } |\xi\rangle_B \succ |\xi\rangle_C) \Rightarrow |\xi\rangle_A \succ |\xi\rangle_C.$$

In this case there is a statistical non-quantum model [7] leading to results identical to those of the discussed here q-bargaining. However, if the polarizations are not constrained by cultural customs or initial agreement they usually are different and it is possible that

$$|\xi\rangle_A \succ |\xi\rangle_B, |\xi\rangle_B \hat{\succ} |\xi\rangle_C \text{ and } |\xi\rangle_C \hat{\hat{\succ}} |\xi\rangle_A$$

An extreme example is the situation when $|\xi\rangle_A \sim |o\rangle$, $|\xi\rangle_B \sim |\widehat{o}\rangle$ and $|\xi\rangle_C \sim |\widehat{\widehat{o}}\rangle$ already known from the popular game *rock, paper and scissors* (RPS). If domination results in profit asymmetry among participants (see below) then traders buying or selling, say, shares issued by companies belonging to Alice, Bob and Carol may be perceived as if playing an RPS game. A quantum version of the RPS game is discussed by Iqbal and Tool [12]. They showed that contrary to the classical case there is a stable Nash equilibrium in the quantum RPS game. The observed non-transitivity of dominance in bargaining is a case in point for using quantum description of bargaining.

Empirical verification should decide if such approach is correct. Of course, one may try to realize q-bargaining games on quantum level where both parties may be formed by coalitions and the appropriate states would be superpositions of states of the members but this is beyond the scope of the present analysis.

4 Rationality of decisions of making bargain

Let us recall that the Alice strategy is, besides its polarization $|\xi\rangle_A \in \mathcal{H}_{sA}$, given by the supply-demand factor $|\psi\rangle_A \in \mathcal{H}_A$ [5]. The total state of q-bargaining, $|\Psi\rangle = |\xi\rangle|\psi\rangle_A|\psi\rangle_B$, belongs to the tensor product of Hilbert spaces $\mathcal{H}_s \otimes \mathcal{H}_A \otimes \mathcal{H}_B$. Let us consider the following situation. Alice is going to buy some commodity at the price c . The random variable $q := -\ln c$ describes the possible profit if the transaction would come true. To be more precise, the additive logarithmic return ratio $\ln \frac{c_0}{c} = \ln c_0 - \ln c$ measures profits made by Alice if the commodity bought at the price c has a real value c_0 to her. If on the other side Bob want to sell the commodity at the price c his potential profits describes the random variable $p := \ln c$. Note that that the supply of an asset at the price c may be perceived as demand of money for which one pays a definite amount of the asset equal to c^{-1} . Therefore there is no minus sign in the definition of the random variable p . The axioms of quantum theory say that the probability density of revealing Alice and Bob intentions described by the random variables q and p , respectively, is given by

$$\frac{|\langle q|\psi\rangle_A|^2}{{}_A\langle\psi|\psi\rangle_A} \frac{|\langle p|\psi\rangle_B|^2}{{}_B\langle\psi|\psi\rangle_B} dqdp, \quad (4)$$

where $\langle q|\psi\rangle_A$ is the probability amplitude of offering the price q by Alice who wants to buy and the demand component of her state is given by $|\psi\rangle_A \in \mathcal{H}_A$. Bob's amplitude $\langle p|\psi\rangle_B$ is interpreted in an analogous way. Of course, the "intentions" q and p not always result in the accomplishment of the transaction. If Alice being in the polarization state $|10\rangle$ offers q that is the price $c = e^{-q}$ then Bob accepts it only if $p \leq -q$ ($e^p \leq e^{-q}$). The symmetry $(q, p, c) \rightarrow (p, q, c^{-1})$ dictates the acceptability condition for Alice in the state $|01\rangle$. The transaction would be accomplished only if Alice pays no more than she plans, $p \leq -q$. Therefore the rationality of the decision does not depend

on polarization and is described by the condition

$$q + p \leq 0 . \quad (5)$$

If we change the convention so that the variable q describes profits of the trading with Alice party instead of hers then the condition (5) takes the form $q + p \geq 0$ with accordingly changed interpretation of p .

Let us use the convenient Iverson notation [14] in which $[expression]$ denotes the logical value (1 or 0) of the sentence *expression*. The logarithm of the transaction price, $\ln c$ is the random variable $-q$ or p depending on the polarization of the transaction ($|10\rangle$ or $|01\rangle$, respectively) restricted by the condition (5). Therefore to obtain the probability density in the state $|10\rangle$ we have to integrate over p the density given by Eq. (4) multiplied by $[q + p \leq 0]$ (Iverson notation)

$$\int_{-\infty}^{\infty} [q + p \leq 0] \frac{|\langle p|\psi\rangle_B|^2}{B\langle\psi|\psi\rangle_B} dp \frac{|\langle q|\psi\rangle_A|^2}{A\langle\psi|\psi\rangle_A} dq \Big|_{q=-\ln c} = \quad (6)$$

$$\int_{-\infty}^{\ln c} \frac{|\langle p|\psi\rangle_B|^2}{B\langle\psi|\psi\rangle_B} dp \frac{|\langle -\ln c|\psi\rangle_A|^2}{A\langle\psi|\psi\rangle_A} d\ln c \quad (7)$$

In an analogous way one gets the distribution of the random variable $\ln c$ for the polarization $|01\rangle$

$$\int_{-\infty}^{\infty} [q + p \leq 0] \frac{|\langle q|\psi\rangle_A|^2}{A\langle\psi|\psi\rangle_A} dq \frac{|\langle p|\psi\rangle_B|^2}{B\langle\psi|\psi\rangle_B} dp \Big|_{p=\ln c} = \quad (8)$$

$$\int_{-\infty}^{-\ln c} \frac{|\langle q|\psi\rangle_A|^2}{A\langle\psi|\psi\rangle_A} dq \frac{|\langle \ln c|\psi\rangle_B|^2}{B\langle\psi|\psi\rangle_B} d\ln c \quad (9)$$

Note that these distribution are not yet correctly normalized.

5 The case when Alice bargains with the Rest of the World

Let us now consider the possible influence of changes in the price character of strategies of bargaining parties on their profits. The analysis of Nash equilibrium states [15] of participants changing their polarizations via strategies being unitary homographies on $\mathbb{CP}_A^1$ i $\mathbb{CP}_B^1$ will be presented in a separate work. To illustrate the course of q-bargaining and the resulting profits let us consider a simple model. Suppose that Alice state is given by a wave

function being a proper function of the demand operator [5]. Then the probability density $\frac{|\langle q|\psi\rangle_A|^2}{A\langle\psi|\psi\rangle_A}$, see Eq. (7) and (9) is given by Dirac delta function $\delta(q-a)$. We interpret it as the strategy *I buy only if the price c lower than e^{-a}* (therefore we call the value e^{-a} the withdrawal price). Let now Carol represent the Rest of the World (*RW*) strategy [5] that is a market on which the good Alice is going to buy fulfills the demand-supply law (is not a *giffen* [5]). Then, according to the theorem discussed in Ref. [5], the probability density $\frac{|\langle p|\psi\rangle_{RW}|^2}{RW\langle\psi|\psi\rangle_{RW}}$ is normal (gaussian). Choosing appropriate units of the good in question and performing the scale transformation $p \rightarrow \sigma p$, where σ is the dispersion leads to the standard normal distribution $\eta(p)$. The formulas (7) i (9) take the following form:

$$\int_{-\infty}^{\ln c} \eta(p) dp \delta(\ln c + a) d \ln c \quad (10)$$

and

$$[\ln c + a \leq 0] \eta(\ln c) d \ln c . \quad (11)$$

The integrals of (10) and (11) over $\ln c \in (-\infty, \infty)$ represent the probability of making q-transaction $E([\ln c + a \leq 0])$ (equal for both polarizations $|10\rangle$ and $|01\rangle$). The time of waiting for accomplishment of the transaction τ is a random variable with a geometrical distribution [13] and does not depend on polarization. Its expectation value is equal to

$$E(\tau) = (1 + E([\ln c + a \leq 0]) \sum_{k=1}^{\infty} k (1 - E([\ln c + a \leq 0]))^{k-1}) \theta \quad (12)$$

$$= (1 + (E([\ln c + a \leq 0]))^{-1}) \theta , \quad (13)$$

where θ is the characteristic (mean) time of duration of q-bargaining [13]. Eq. (12) respects the time Alice needs for selling the good (also equal to θ). This is a consequence of her strategy $\delta(q-a)$. The profit Alice made in a sequence identical of q-bargaining is measured by the profit intensity equal to [15]

$$- \frac{p_{10} E_{10}(\ln c) + (1 - p_{10}) E_{01}(\ln c)}{E(\tau)} , \quad (14)$$

where $p_{10} := |\langle 10|10\rangle|^2$ is the probability of making the transaction with polarization $|10\rangle$. The distributions (10) and (11) are not normalized so the averaging $E_{10}()$ and $E_{01}()$ should be performed with appropriately normalized

distributions (10) i (11), that is $\delta(\ln c + a)d \ln c$ and $\frac{[\ln c + a \leq 0]}{E([\ln c + a \leq 0])}\eta(\ln c)d \ln c$. By combining Eq. (14) and Eq. (12) and multiplying both the numerator and denominator by $E([\ln c + a \leq 0])$ we get the following function $\rho(a)$ giving the Alice profit intensity (in units of θ)

$$\rho(a) = \frac{\int_{-\infty}^{-a} (p_{10}a - p_{01}x)\eta(x)dx}{1 + \int_{-\infty}^{-a} \eta(x)dx} \quad (15)$$

Figure 1: Alice profit intensity in q -bargaining with RW as a function of logarithm of withdrawal price $a \in [-2.5, 2.5]$ and probability p_{01} of q -bargaining being in the state $|01\rangle$.

In the case when Rest of the World always decides to make the transaction ($p_{10} = 1$) the maximal profit intensity Alice may get is equal 0.14028 and corresponds to the withdrawal price a equal to 0.85096. If on the other hand Rest of the World always proposes the price then Alice get the maximal profit intensity for the strategy $a = 0.27063$. This value has the property of being a fixed point of the function $\rho(a)$ (ρ is a contraction almost everywhere) [13]. Therefore if Alice does not know the parameters of the RW distribution her best method of achieving the condition $a = 0.27063\sigma$ in a polarization state $|01\rangle$ is the simple iteration $\rho(a) \rightarrow a$ leading to self-correcting optimal algorithm for getting the withdrawal price a . In the discussed q -bargaining the polarization $|01\rangle$ is more profitable for Alice than $|01\rangle$. The characteristics of

q-bargaining are presented in Fig. 1 (diagram of the function $\rho = \rho(a, p_{10})$). If $p_{01} = 1$ then any value of a brings non-zero average profits. On the other hand, if the q-bargaining has the polarization $|10\rangle$ (that is $p_{01} = 0$) any strategy with $a < 0$ results in losses. Therefore we should not be surprised that rivalry among sellers resulted in a market where sellers display prices to give their potential clients better bargaining positions.

6 Temperatures of mixtures of q-bargaining

General quantum bargaining involves mixed strategies and therefore should be described in terms of probability density matrix (operator) ρ defined on the Hilbert space $\mathcal{H}_s \otimes \mathcal{H}_A \otimes \mathcal{H}_B$. Cases when the polarization of q-bargaining does not depend on mutually independent mixed strategies of Alice and Bob should be described by factorized density operators of the form $\rho = \rho_s \rho_A \rho_B$, where ρ_s is defined in $\mathcal{H}_s$, ρ_A in $\mathcal{H}_A$, and ρ_B in $\mathcal{H}_B$. The polarization state of q-bargaining, ρ_s , is now a convex linear combination of pure states $P_{\vec{T}}$ belonging to S^2 given by

$$\rho_{\beta_s, \vec{T}} = \frac{e^{\frac{\beta_s}{2} \vec{T} \cdot \vec{\sigma}}}{\text{Tr}(e^{\frac{\beta_s}{2} \vec{T} \cdot \vec{\sigma}})} = \frac{1}{2} \left(I + \vec{T} \cdot \vec{\sigma} \tanh \frac{\beta_s}{2} \right), \quad (16)$$

where Tr denotes trace and $\beta_s \in \mathbb{R}$ is the inverse of spin temperature of the system described by the density operator $\rho_{\beta_s, \vec{T}}$. The above formula may be simplified by substitution $\frac{\beta_s}{2} \rightarrow \beta_s$ but our convention leads to formulas consistent with those performed in the two-dimensional representation of the Lie algebra $su(2)$. It follows from Eq. (16) that the limits of ρ are projections

$$\lim_{\beta_s \rightarrow \infty} \rho_{\beta_s, \vec{T}} = \lim_{\beta_s \rightarrow -\infty} \rho_{\beta_s, -\vec{T}} = P_{\vec{T}}.$$

Let us suppose that $\beta_s \geq 0$ in order to get unambiguous parameterization of the unit ball K^2 (apart from the center). We may identify every polarization state $\rho_{\beta_s, \vec{T}}$ with some point $\rho \in K_2$. Strait lines joining those points with the center cut the sphere S_2 at two antipodal points $-\vec{T}$ and $\vec{T}$. The proportion of the division of the segment $\{-\vec{T}, \vec{T}\}$ by ρ determines for every polarization state coefficients of its representation as a convex combination of two projections

$$\rho_{\beta_s, \vec{T}} = \frac{P_{\vec{T}}}{1 + e^{-\beta_s}} + \frac{P_{-\vec{T}}}{1 + e^{\beta_s}}.$$

This construction may be performed even if $\beta=0$ when ρ is the center of K^2 but then the direction of $\vec{\tau}$ is undetermined. There is another important quantity, namely Shannon entropy S , that, instead of spin temperature, may be used to parameterize polarization states. In our case Shannon entropy is given by

$$S(\beta_s) = -\text{Tr}(\rho_{\beta_s, \vec{\tau}} \ln \rho_{\beta_s, \vec{\tau}}) = \frac{\ln(1 + e^{\beta_s})}{1 + e^{\beta_s}} + \frac{\ln(1 + e^{-\beta_s})}{1 + e^{-\beta_s}}.$$

The present authors introduced in Ref. [13] risk temperature, being the inverse of Legendre multiplier β . There is the following relation between the dispersion σ and the risk temperature β^{-1} of the discussed above demand-supply part of strategy of the Rest of the World (normal distribution)

$$\sigma^2 \tanh \frac{h_E \beta}{2\theta} = \text{const.}$$

Here h_E is the economic analogue of Planck constant. In q-bargaining the temperature of Alice strategy is zero because her strategy may be perceived as the limit of the normal distribution with dispersion tending to zero. This allows her to perform arbitrage. The only remedy for limiting Alice profits in trading with the Rest of the World consists in the lowering of the RW dispersion σ , that is the risk temperature β^{-1} . As a result the optimal value of the parameter a of Alice strategy will be shifted towards zero. Alice, to correct her strategy, have to start a new iterative procedure to find the new optimal value of a and this will enlarge dispersion of her strategy ($\beta_{Alice}^{-1} > 0$). This process resembles heat transfer from a hot thermostat (RW) to a cold one (Alice). As a result the thermostat RW cools down. Alice gets warmer and subsequently while finding new value of a lowers her temperature (and entropy).

If we introduce a mechanism of coupling polarization of RW with its demand-supply part $\eta(p)$ being an integral Wigner function with Gibbs weights [5], we would get a model analogous to spin system interacting with phonon thermostat [16]. We envisage the investigation of q-bargaining with methods characteristic to quantum quasi-equilibrium stochastic processes. This should result in formulation of nonlinear equations governing the dynamics of changes in risk and spin temperatures. But investigation of q-bargaining without the underlying thermostat RW that dictates market prices seems to

be to abstract for application in economics. It is customary that the polarization state in bargaining with the Rest of the World is fixed in advance (e.g. sellers price). Therefore nontrivial description of changes in spin temperature of q -bargaining may be obtained only in models with at least three parties: A, B and RW with A and B using different strategies with respect to themselves than to RW . Such a minimal model is four-dimensional and describes risk temperatures of A, B and RW and spin temperature of the q -bargaining between A and B.

Note that spin temperature resembles another Legendre multiplier connected to portfolio managing and introduced and discussed in Ref. [17]. Such coupled to the logarithmic rate of return portfolio temperature (third kind of temperature of economic process!) allows to compare skills of investors active in different market or market conditions and not necessary during the same intervals. For an aggressive market activity the logarithmic rate of return cease to be additive and portfolio temperatures acquire nonzero imaginary parts [11]. The considered above q -bargaining between Alice and RW with both polarizations may be perceived as multiple buying and selling of some financial asset with normal distribution of quotation of logarithm of its price. So we are able to determine the portfolio temperature of Alice strategy. Such thermodynamics of q -bargaining between Alice and RW would be presented elsewhere.

7 Final remarks

If Bill intervene in q -bargaining between Alice and Bob so that first transaction is made between Alice and Bill and the second between Bob and Bill then we may call the process complex q -bargaining between Alice and Bob. The middlemen (e.g. Bill) are filters from the quantum mechanical point of view. In complex q -bargaining one may give up clearing of the intermediate transactions. This would result in superposition of amplitudes characterizing profits (logarithm of prices) and polarizations of complex q -bargaining.

The discussed connection between q -bargaining and condensed matter physics suggest that q -bargaining might be performed with help of quantum automata. If Penrose is right in his suggestions concerning the process of thinking [18] the phenomenon of q -bargaining might be possible to detect in

present markets where transactions are made due to non-computational algorithms. Does a middleman performs the role of a "polarizator" facilitating making transactions?

If we consider more realistic market of several assets then q-bargaining will concern many price-like parameters $c_1, c_2, \dots$. So q-bargaining may be used for modeling negotiations based on multi-criterion valuation of the offer.

Ancient Greeks, already 800 years BC, knew that the polarization $|01\rangle$ is more profitable for Alice, that is she accepts the transaction instead of proposing the price. Heziod writes [19] that Zeus accepting the method *one divides the other chooses* in his deal with Prometheus, let the human to divide.

Acknowledgments. The authors would like to thank dr. J. Eisert for stimulating and helpful discussions.
